Seasonal variations of the composition of microbial biofilms in sandy tidal flats: Focus of fatty acids, pigments and exopolymers

Claire Passarelli, Tarik Meziane, Najet Thiney, Dominique Boeur, Bruno Jesus, Mickael Ruivo, Christian Jeanthon, Cédric Hubas

1. Introduction

In coastal soft-bottom areas, a large diversity of microbial mats exists; their composition depends on environmental conditions such as salinity, tidal height and duration of exposure, light, grain size, and organic matter input (Brotas et al., 1995; Paterson and Hagerthay, 2001; Franks and Stolz, 2009). Additionally, they are sensitive to anthropic actions such as eutrophication or antibiotic release in the environment (Lubarsky et al., 2012; Sawall et al., 2012). These biofilms are often very productive and they also provide different ecosystem services, such as nutrient recycling, degradation of pollutants and sediment stabilisation, and they are essential for the recruitment of numerous benthic organisms (Decho, 2000).

Biofilms consist of microorganisms embedded in a matrix of extracellular polymeric substances (EPS), which are produced by the different organisms of the biofilm. These EPS are chemically diverse molecules but are mainly composed of carbohydrates and...
protein, and contain very few lipids. EPS have various roles for microorganisms: they protect from pollutants and desiccation (Decho, 1990; Potts, 1994) and they allow locomotion, especially for diatoms, and attachment to sediment (Wotton, 2004). They are also important for coastal systems, as they are for instance responsible for sediment stabilisation in intertidal areas (Decho, 1990).

Because their composition varies depending on their environment, microbial mats are useful as proxies of environmental conditions. Therefore, various markers have been developed to characterise the microbial composition of biofilms and, more recently, their EPS composition. Quantification of carbohydrates and proteins has been a first step, and GC–MS and LC-MS (gas and liquid chromatography coupled with mass spectrometry) now allow a further analysis of these molecules. Carbohydrates in particular have been investigated as they are crucial for sediment stabilisation by biofilms (de Brouwer et al., 2005); these molecules have been characterised through their monosaccharide composition, which has been shown to vary according to organisms and environmental conditions (de Brouwer and Stal, 2002; Underwood et al., 2004; Hanlon et al., 2006).

Due to the numerous roles of EPS in coastal systems, and given that these roles depend on EPS composition, characterising EPS composition and variations is an important challenge to understand the provision of ecosystem services by microbial mats in varying environments. Therefore, this study was designed to test the hypothesis that the EPS composition of biofilms: (1) varies seasonally and is influenced by other environmental conditions; and (2) does not only depend on the microorganisms forming the microbial mats. Biofilms were followed over the year on-field in an intertidal area, in three experimental conditions. Artificial tubes mimicking polychaete tubes were used to modify biofilm development, as such tubes influence both microbial expansion and EPS production (Passarelli et al., 2012). Biofilms were sampled monthly and the microbial assemblage was characterised by their fatty acid and pigment contents. EPS were characterised by the monosaccharide composition of their carbohydrates.

2. Material and methods

2.1. Study site

Experiments were carried out from March 2011 to April 2012 in the Chausey archipelago (France) within the Normand-Breton Gulf (English Channel), which is characterized by a megalitidal regime (tidal range up to 14 m). The Chausey archipelago includes 1500 ha of soft sediment tidal flats.

2.2. Experimental design

Twelve cylindrical benthic chambers of 300 mm inner diameter and 60 mm depth were placed in the intertidal sandy area of Chausey archipelago (Normand-Breton Gulf, France). Solid PVC cylindrical rods were fixed to the bottom of each benthic chamber, simulating tubes of large polychaete "builder" species, such as Lanice conchilega or Melinna cristata (5 mm diameter, 95 mm length). Three treatments were used (4 replicate chambers per treatment); a control treatment (Ctrl), without tubes; then 2 test treatments with varying densities of evenly spaced tubes: a low density (LD) treatment (637 tubes m$^{-2}$) and a high density (HD) treatment (2505 tubes m$^{-2}$). The LD treatment potentially destabilised the sediment (i.e. initiated interactive flow; Friedrichs et al., 2000), whereas the HD treatment most likely had a stabilising effect on it (i.e. initiated skimming flow; Friedrichs et al., 2000).

These densities were both within the range of natural densities for polychaete tubes (up to 5000 ind m$^{-2}$; e.g. Friedrichs et al., 2000 for M. cristata).

Before positioning the chambers in the field, they were filled with defaunated sand (washed with 1 mol l$^{-1}$ HCl, frozen and thawed) collected at the study site (medium sand, median grain size between 260 and 300 μm). They were then placed into the intertidal area on 21 March 2011, with a 2 m gap between chambers. Sampling was carried out approximately every month (14 times in the experiment, depending on tidal height and accessibility of the study site) from the beginning of the experiment to 8 April 2012.

Sampling locations within the chambers were randomly chosen for each sampling time, taking care that a single location was never sampled twice in a 3-month period.

Visual observation of the plots confirmed that any cavities created by sampling were filled by natural sediment within 24 h, after which no trace of the sampling was apparent.

2.3. Sampling and measurements

2.3.1. Fatty acids composition of the sediment

One sample was taken from each benthic chamber at every sampling date (2 cm inner with mesh cut off syringe, 1 cm depth). Sediment cores were frozen and transported back to the laboratory where they were freeze-dried, and stored at −26 °C. 400−500 mg of sediment were weighted and used for the analysis. Fatty acid (FA) analysis was performed following the modified method of Bligh and Dyer (1959) as described in Mortillaro et al. (2011). Before extraction, an internal standard (FA 23:0) was added to every sample for quantification purpose. Lipids were extracted with a 20 min ultrasonication in a mixture of distilled water, chloroform and methanol in ratio 1:1:2 (v:v:v). Lipids were concentrated under N$_2$ flux, and saponified, in order to separate FAs, with a mixture of NaOH (2 mol l$^{-1}$) and methanol (1:2, v:v) at 90 °C during 90 min. Saponification was stopped with hydrochloric acid. FAs were then derivatized with BF$_3$-methanol (boron trifluoromethanol) at 90 °C during 10 min and kept frozen in chloroform. Just before analysis, samples were dried under N$_2$ flux and transferred to hexane. One μl of the mixture was injected in a gas chromatograph (GC, Varian CP-3800 equipped with flame ionization detector), which allowed separation and quantification of FAs. Separation was performed with a Supelco OMEGAWAX 320 column (30 m × 0.32 mm i.d., 0.25 μm film thickness) with He as carrier gas. The following temperature program was used: 60 °C for 1 min, then raise to 150 °C at 40 °C min$^{-1}$ (held 3 min), then raise to 240 °C at 3 °C min$^{-1}$ (held 7 min). Peaks of FAs were identified by comparison of the retention time with analytical standards (Supelco™, PUFA-1 Marine Source, and Bacterial Mix, Supelco Inc., USA) and analysis of the sample in a gas chromatograph coupled to mass spectrometer (GC–MS, Varian 450GC with Varian 220-MS).

FAs are designated as X:Y,Z, where X is the number of carbons, Y the number of double bonds and Z the position of the ultimate double bond from the terminal methyl.

2.3.2. Pigment composition of the sediment

Three samples were taken from each benthic chamber at every sampling date (2 cm inner diameter cut off syringe, 1 cm depth), and pooled. Samples were kept frozen at −26 °C until analysis. Pigments were extracted from a sub-sample of approximately 0.2 g of freeze-dried sediment with 2 ml of 95% cold buffered methanol (2% ammonium acetate) for 15 min at −20 °C in the dark. Samples were sonicated for 30 s at the beginning of the extraction period. Extracts were filtered with Whatman membrane filters (0.2 mm) immediately before HPLC analysis. Pigment extracts were analysed...
using a Shimadzu HPLC comprised of a solvent delivery module (LC-10ADVP) with system controller (SCL-10AVP), a photodiode array (SPD-M10A VP) and a fluorescence detector (RF-10AXL). Chromatographic separation was carried out using a C18 column for reverse phase chromatography (Supelcosil, 25 cm long, 4.6 mm in diameter, and 5 μm particles). The solvents used were 0.5 mol L⁻¹ ammonium acetate in methanol and water (85:15, v:v), acetonitrile and water (90:10, v:v), and 100% ethyl acetate. The solvent gradient followed Kraya et al. (1992) with a flow rate of 0.6 ml min⁻¹ and an injection volume of 100 μl. Identification and calibration of the HPLC peaks was confirmed with chlorophyll a, chlorophyll b and β-carotene standards from Sigma and chlorophyll c, fucoxanthin, diadinoxanthin, diatoxanthin, lutein, zeaxanthin, and phaeophytin a standards from DHI. Pigments were identified by the absorption spectra and retention times and the concentrations calculated from the signals in the photodiode array (chlorophylls and carotenoids) or fluorescence detector (pheophorbides and pheophythin s). As samples were not frozen in situ but transported in the dark before being frozen, diatoxanthin had time to revert to diadinoxanthin. Therefore, concentrations of diatoxanthin and diadinoxanthin were added and analysed together as xanthophyll concentration.

2.3.3. EPS composition in monosaccharides

Three samples were taken from each benthic chamber at every sampling date (2 cm inner diameter cut off syringe, 1 cm depth), pooled onto one sample per chamber, and frozen until analysis. Monosaccharide composition of carbohydrates was determined using gas chromatography (GC), following a method adapted from Pierre et al. (2010). Briefly, EPS were extracted, and carbohydrates decomposed into monosaccharides with acidic hydrolysis. Sugars were thereafter silylated and separated with GC. Colloidal EPS were extracted by rotating the samples in artificial sea water (30 g l⁻¹) 1 h at 4 °C. Bound EPS were thereafter recovered by adding resin (Dowex Marathon C, sodium form, Sigma) to the remaining sediment and performing a second extraction. Both fractions were dialysed against distilled water (12–14 kDa) and freeze-dried. EPS were dissolved in 2 mol L⁻¹ HCl, and heated 4 h at 90 °C. The solution then mainly contained monosaccharides, and was freeze-dried again.

Silylation was performed with a mixture of BSTFA:TMCS (N,O-bis(trimethylsilyl)trifluoroacetamide and trimethylchlorosilane, 100:1, Sigma) and pyridine (1:1, v:v), 2 h at room temperature. After the silylation, 1 μl of the sample was injected in GC (GC, Varian CP-3800 equipped with flame ionization detector), which allowed separation and relative quantification of sugars. Separation was performed with an Agilent Technologies VF-1701 ms column (30 m × 0.32 mm i.d., 0.25 μm film thickness) with He as carrier gas. The following temperature program was used: start at 150 °C, raise to 200 °C at 7 °C min⁻¹ (held 5 min). Injector temperature was set at 250 °C. Peaks of monosaccharides were identified by comparison of the retention time with analytical standards (rhamnose, fucose, xylose, mannose, galactose, glucose, scyllo- and myo-inositol, galacturonic and glucuronic acid), which had been prepared (silylation and injection only) as samples. Carbohydrate and protein concentrations in EPS were measured by colorimetry following methods from Lubarsky et al. (2010).

2.4. Statistical analyses

Non-parametric statistics under the R statistical framework were used for univariate analyses as data violated assumptions of homogeneity of variance and normality. Differences between treatments were assessed by Kruskal–Wallis tests (KW), while differences between sampling time for each treatment were assessed by Friedman tests (considering data from each chamber as paired data).

Non-metric MultiDimensional Scaling (nMDS) analyses (500 iterations) were performed with similarity matrix constructed with Bray Curtis distances for FAs, pigments and sugars. These graphical representations show similarity between samples: the closer the symbols are in the representation, the closer the characteristics of the samples are. 2-factor ANOSIMs (crossed factors: Time and Treatments) were then used to assess the differences between assemblages from different sampling times (Primer 5 software, 10,000 iterations), and variables responsible for such differences were investigated with SIMPER analyses.

Multiple Factor Analysis (MFA) was performed to compare chambers at different sampling time using FA, pigment and sugar datasets. MFA studies several groups of variables defined on the same set of individuals. The core of the method is a factor analysis applied to the whole set of variables, in which each group of variables is weighted so that no group of variables become dominant over the others (Escoffier and Pagès, 1994). Data were scaled to unit variance.

3. Results

3.1. Composition of the microbial community

3.1.1. Fatty acid contents

Overall compositions of microbial communities and organic matter in sediment was assessed through their fatty acid (FA) content. Quantitative data (Fig. S1) showed accumulation of FAs in sediment in early August and late September. FAs found in our sediment samples are listed on table S1. Most abundant FAs were saturated FAs (SFAs) 14:0, 16:0, 18:0, mono-unsaturated FA (MUFA) 16:1ω7 and polyunsaturated FA (PUFA) 20:5ω3, suggesting a large abundance of diatoms in these biofilms. Moreover, branched FAs (BFAs) reached a 2% relative contribution, showing the presence of heterotrophic bacteria.

Data showed a dramatic change in FA composition of sediment through time (Fig. 1; ANOSIM: R = 0.767, p < 0.001). Samples from two following months were significantly different one from each other’s, except in winter where samples were similar (ANOSIM post-hoc pairwise tests, Table 1). SIMPER analysis showed that FAs 16:1ω7 and 20:5ω3, as well as saturated FAs (SFAs; mainly 14:0, 16:0 and 18:0) were responsible for the differences between time groups. Namely, proportions of 16:1ω7 and 20:5ω3 varied significantly through time in every treatment (Friedman tests, p < 0.001); they were present in higher proportions in April, May, at the beginning of August, in some samples of November and from January to March 2012, compared to other months. On the contrary, the ratio between saturated and polyunsaturated FAs (SFA/PUFA ratio) was lower in these months.

Samples were also significantly different between treatments (ANOSIM, R = 0.284, p < 0.001; ANOSIM post-hoc pairwise tests Table 2), although the time effect seemed predominant (Fig. 1). Main differences were explained by MUFA 16:1ω7, PUFA 20:5ω3 and SFA 18:0, which were more abundant in Ctrl treatments compared to others; by SFA 14:0 which was more abundant in both treatments with tubes; and by SFA 16:0 which accumulated more in LD chambers.

3.1.2. Pigment contents

Overall composition of the photosynthetic communities in sediment was assessed through their pigment content. Total pigment concentrations (Fig. S2) showed accumulation in summer (LD treatments) or after summer (other treatments). Sediment samples contained mainly chlorophyll a, fucoxanthin, alloxanthin...
and chlorophyll c (Table S2), showing the preponderance of diatoms and cryptophytes.

Pigment composition of sediment also changed through time (Fig. 2; ANOSIM: \( R = 0.393, p < 0.001 \)). Significant differences between two following months mostly appear in late summer, at the beginning of autumn and in winter (ANOSIM post-hoc pairwise tests, Table 1). Regardless of the sampling time, chlorophyll \( a \) accounted for approximately 50% of pigments in sediment, while proportions of fucoxanthin and alloxanthin exhibited significant differences among time (Friedman tests, \( p > 0.05 \) for chlorophyll \( a \) and \( p < 0.05 \) for fucoxanthin and alloxanthin). Pigments contributing highly to dissimilarities between seasons were chlorophylls \( a \) and \( c \), which were in higher proportions in autumn and winter, and chlorophyllide \( a \) and xanthophylls, which were in higher proportions in spring and summer.

Pigment composition of sediment changed weakly between treatments (ANOSIM: \( R = 0.08, p = 0.016 \)): chambers with tubes had significantly different compositions compared to control chambers (ANOSIM post-hoc pairwise tests, Table 2). Chlorophyllide \( a \) was indeed in lower proportion and alloxanthin in higher proportion in Ctrl chambers compared to other chambers.

### Table 1

Results of ANOSIM pairwise post-hoc tests comparing consecutive months (e.g. May with April and June) using 4 sets of markers: fatty acids, pigments, colloidal and bound sugars. All 12 samples (pooled from all 3 treatments) from each sampling times were used. Test significance: ns: not significant; *: \( p < 0.05 \); **: \( p < 0.01 \); ***: \( p < 0.001 \). Coll: colloidal. Aug: August; Sept: September; Oct: October; Nov: November; Jan: January; Feb: February; Mar: March; Apr: April.

3.2.2. EPS fractions

Colloidal and bound fractions (Friedman tests, \( p < 0.001 \)), with highest contributions in summer.

Therefore, the analysis was made separately for colloidal and bound EPS fractions.

3.2.3. Colloidal EPS

Monosaccharide composition of colloidal EPS changed through time, with significant differences between sampling months (Fig. 3; ANOSIM: \( R = 0.375, \ p < 0.001 \)). Periods of variations were distributed along the year (ANOSIM post-hoc tests, Table 1). Sugars explaining most dissimilarity between sampling times were the most abundant: glucose, mannose and galactose, as well as scyllo-
in our study. Also, our sampling protocol, which includes a freezing step, might prompt release of intracellular material, especially of glucose, especially in bound fractions where percentage reached 20% of total monosaccharide only. This difference could originate from a different producing community, for instance epipelic assemblages instead of epipsammic ones, as they analysed mud instead of sand in our study. Also, our sampling protocol, which includes a freezing step, might prompt release of intracellular material, especially of some chrysolaminarin, which is an intracellular storage glucan in diatoms, mainly composed of glucose (Chiovitti et al., 2004; Underwood et al., 2004). Other abundant monosaccharides were mannose and galactose, which is consistent with observation made on Cylindrotheca closterium cultures (Underwood et al., 2004). The large amounts of glucose, mannose and galactose present in our sediment samples suggest that organic matter was mostly fresh, as these three sugars are particularly labile (Oakes et al., 2010).

4. Discussion

4.1. EPS composition over the course of the experiment

4.1.1. Composition of carbohydrates in colloidal and bound EPS

EPS were divided in two fractions according to their extraction protocol: the colloidal fraction was extracted with water only whereas bound EPS were collected with a strong cationic resin (Takahashi et al., 2009). This resin traps the cations maintaining the links between bound EPS, therefore allowing their release in the water. Our results demonstrate that these two EPS fractions are chemically different, as their monosaccharide general compositions are significantly different. These two compositions of colloidal and bound EPS do not change simultaneously along the year (Table 1), suggesting that their control is specific to each EPS fraction. These different compositions are consistent with literature data showing that both fractions have different production and degradation pathways (Staats et al., 1999; Underwood and Paterson, 2003).

Most abundant sugars were the same, but in different proportions, in both fractions. EPS carbohydrates consisted mostly in glucose, which always reached percentages over 50%. Colloidal EPS contained more glucose than bound EPS, which is consistent with literature data (Taylor et al., 1999; Hofmann et al., 2009; Pierre et al., 2010). Yet, Pierre et al. (2010) obtained lower percentages of glucose, especially in bound fractions were percentage reached 20% of total monosaccharide only. This difference could originate from a different producing community, for instance epipelic assemblages instead of epipsammic ones, as they analysed mud instead of sand in our study. Also, our sampling protocol, which includes a freezing step, might prompt release of intracellular material, especially of some chrysolaminarin, which is an intracellular storage glucan in diatoms, mainly composed of glucose (Chiovitti et al., 2004; Underwood et al., 2004). Other abundant monosaccharides were mannose and galactose, which is consistent with observation made on Cylindrotheca closterium cultures (Underwood et al., 2004). The large amounts of glucose, mannose and galactose present in our sediment samples suggest that organic matter was mostly fresh, as these three sugars are particularly labile (Oakes et al., 2010).

4.1.2. Variations in EPS compositions

Both bound and colloidal carbohydrates displayed seasonal variations in their monosaccharide composition. Glucose was mainly responsible for seasonal differences; it accumulated in summer and was recorded in lower proportions in other seasons. Higher percentages of glucose in EPS have been correlated with
photosynthetic production (de Brouwer and Stal, 2001; Bellinger et al., 2005; Hanlon et al., 2006). Also, in the studied sediments, the increase in glucose proportion in summer may originate from the degradation of intracellular chrysolaminarin, released in the environment by senescent diatoms. Other seasons displayed a higher diversity of sugars, which could be explained by the preferential degradation of glucose by heterotrophic bacteria (Bellinger et al., 2005; Hofmann et al., 2009): particularly, fucose, rhamnose and galactose are known to be more difficult for them to assimilate than glucose (Giroldo et al., 2003). Finally, nutrient concentrations and galactose are known to be more differential degradation of glucose by heterotrophic bacteria (Bellinger et al., 2005; Hofmann et al., 2009): particularly, fucose, rhamnose and galactose, and pentoses seem to promote biostabilisation of sediment (Bellinger et al., 2009). Additionally, deoxy-sugars such as fucose and rhamnose, and pentoses seem to promote biostabilisation of sediment (Bellinger et al., 2009). Additionally, deoxy-sugars such as fucose and rhamnose, and pentoses seem to promote biostabilisation of sediment (Bellinger et al., 2009).

Colloidal EPS compositions were not influenced by experimental conditions, while the composition of bound carbohydrates appeared to vary between treatments: chambers with high tube density had different sediment composition compared to other chambers. Such effect might result from a direct influence of hydrodynamics on EPS production, or from an indirect influence of tubes on benthic assemblages, or from a combination of both. As microbial assemblages and bound EPS compositions do not display similar temporal evolutions (Table 1), a direct effect of hydrodynamics on the production or degradation of bound EPS is a likely hypothesis. With such mechanisms, microorganisms could better adapt their adhesion to the local current conditions. For instance, deoxy-monosaccharides like rhamnose and pentoses like xylose are able to promote adhesion to sediment because of their hydrophobicity (Bellinger et al., 2009).

4.1.3. Functionality of different sugars

Pierre et al. (2010) revealed the presence of myo-inositol in carbohydrates of marine sediment; this sugar is crucial for the functioning of many eukaryotic cells and is also a growth factor for various organisms. Our sediment samples also contained this sugar, and additionally its stereoisomer: scyllo-inositol. To our knowledge, this monosaccharide has never been found in EPS carbohydrates. In diatoms, it may originate from myo-inositol after transformation by the myo-inositol deshydrogenase enzyme (Gross and Meyer, 2003), which may explain its presence in the biofilm. Also, this monomer was an important sugar in separating winter from other seasons, which might be explained by variations in the functioning of this enzyme, although its role is still under investigation (Gross and Meyer, 2003). In soils, scyllo-inositol is associated to phosphate in scyllo-inositol hexakisphosphate, which forms an important part of the organic phosphorus content (Turner et al., 2005).

When studying different mudflats, de Brouwer et al. (2003) showed that EPS mainly originated from refractory dissolved organic matter. This is probably not the case here, as monosaccharide composition revealed a high proportion of glucose in every sample. Sugar composition can therefore be interpreted in terms of functionality for microorganisms. For instance, uronic acids have acidic groups which provide sites for sediment–organism interactions, so that they facilitate the fixation of cells to sediment (Bellinger et al., 2009). Also, deoxy-sugars such as fucose and rhamnose, and pentoses seem to promote biostabilisation of the sediment by enhancing the hydrophobicity of the biofilm (Zhou et al., 1998; Bellinger et al., 2009). Finally, differences in monosaccharide composition have been shown to promote the development of different bacterial communities, depending on the ability of different bacterial groups to degrade these carbohydrates (Taylor et al., 2013). Changes in EPS composition and bacterial population will in turn provide recruitment cues for diverse organisms and can therefore facilitate or hinder the resilience of ecosystem engineers (Nelson et al., 2013).

4.2. EPS and microbial communities

4.2.1. Fatty acid biomarkers

In the studied environment, external factors varying seasonally such as temperature, photoperiod, and hydrodynamics have a
strong structuring influence on EPS composition. EPS composition is also impacted by the composition of producing assemblages (Decho, 1990), which were in the present work characterised by their fatty acid (FA) and pigment compositions. FAs are ubiquitous to all living organisms, but most taxonomic or functional groups are characterised by a given association of some FAs. For instance, branched FAs are only produced by bacteria (Arts and Wainman, 1999). Description of FA content of sediment provides, together, information on taxonomic or functional groups and on the degradation state of organic matter. The increase of SFA percentages, and of its ratio to PUFAs, demonstrates an accumulation of degraded OM in sediments in summer and autumn (Sun et al., 1997; Grossi et al., 2006). On the other hand, spring and winter months, as well as the beginning of August, are characterised by higher MUFA and PUFAs percentages; in particular, MUFA 16:1\text{u}7 and PUFA 20:5\text{u}3 (or EPA for eicosapentanoic acid) relative contributions showed a drastic increase in these months. These FAs are mainly produced by microphytobenthos in these environments, especially diatoms, dinoflagellates and cyanobacteria (Volkman et al., 1980; Arts and Wainman, 1999). Yet the association of MUFA 16:1\text{u}7 and PUFA 20:5\text{u}3 together with high amounts of SFA 14:0 and 16:0 suggest a dominance of diatoms (Dijkman et al., 2010).

4.2.2. Pigment biomarkers

Pigments were used to characterise the abundance and taxonomic composition of microphytobenthic communities. The abundance of fucoxanthin, together with chlorophylls a and c, is consistent with results of FA analysis in demonstrating the prevalence of diatoms in this environment (Jeffrey et al., 1997). Also, the presence of alloxanthin shows the occurrence of cryptophytes (Jeffrey et al., 1997). Proportions of chlorophylls c and fucoxanthin displayed a seasonal pattern, being higher in autumn and winter compared to spring and summer; on the contrary, chlorophyllide a showed a reversed pattern. This last pigment reveals the occurrence of senescent diatoms (Jeffrey et al., 1999), which suggests a higher predation rate in these months. Also, the occurrence of chlorophyllide a might be related to an exogenous supply of pigment. Xanthophylls displayed the same seasonal pattern than chlorophyllide a, which can be explained by their role in the xanthophyll cycle, which act as a photoprotection mechanism (Jeffrey et al., 1997); in spring and summer months, when light intensity increases, xanthophyll production increases, and dia-dinoxanthin in transformed into diatoxanthin.

4.2.3. Multi-marker approach and general dynamic of the biofilm

When combining datasets of FAs and pigments together with those on EPS composition (Fig. 5), samples from every month clearly gathered together, showing a well-defined temporal evolution. Also, this analysis highlights the association between variables and samples, which allows following the dynamics of the biofilm in the course of year and to link EPS composition with microorganisms.

In winter time, the sediment contained high proportions of fucoxanthin and chlorophyll c, which indicated the development of diatoms (Jeffrey et al., 1997); in the meantime, proportions of most sugars except glucose, particularly galactose and mannose in both EPS fractions, and scyllo-inositol in colloidal EPS, increased. In spring, the abundance of diatoms increased, as demonstrated by increase in 16:1\text{u}7 and 20:5\text{u}3 biomarkers (Dalsgaard et al., 2003). Also, the increase of alloxanthin proportions together with 18:4\text{u}3 FAs mirrored the development of cryptophytes. In late spring, xanthophyll proportions increased, as a protection against light intensity for diatoms (Jeffrey et al., 1997). Summer was characterised by high amounts of most saturated FAs, which indicates the accumulation of degraded organic matter (Sun et al., 1997; Lü et al., 2010; Balzano et al., 2011). This degradation is emphasised by the presence of chlorophyllide a which indicates the presence of senescent diatoms (Jeffrey et al., 1999); these organisms may then release in the environment high amounts of intracellular chrys-olaminarin, explaining the increase of glucose proportions in both EPS fraction in summer. Some glucose may also originate from higher photosynthetic production in late spring and in the beginning of summer, when light intensity, photoperiod and temperature increase. Finally, autumn is characterised by high levels of markers of bacterial degradation: phaeophytin a which results from the degradation of chlorophyll (Lorenzen, 1967) as well as most branched FAs, which characterise heterotrophic bacteria (Arts and Wainman, 1999).

Results of analyses on separate datasets showed no correlation between the periods where microbial assemblages change and those where EPS composition does so (Table 1). However, our multi-marker analysis suggested links between EPS composition and biological processes taking place in the sediment, such as photosynthesis, which depend on microbial assemblages. For instance, the large increase of glucose contribution in summer was linked to the degradation of senescing diatoms evidenced by chlorophyllide a. Finally, it seems that EPS composition of sediment is influenced at the same time by the succession of microbial assemblages taking place in tidal flats and directly by environmental conditions.

5. Conclusion

In this study, association of FA and pigment biomarkers together with monosaccharide composition of EPS complemented each other to allow a fine characterisation of the biofilm in the course of year, describing its composition and functioning. Furthermore, as different monosaccharides may be associated with different ecosystem functions (stabilisation, recruitment cues for instance; Bellinger et al., 2009; Nelson et al., 2013; Zhou et al., 1998), this set of variables may indicate diverse roles of biofilms for the ecosystem.

Acknowledgement

The authors thank two anonymous reviewers whose advice and comments greatly improved the manuscript. We thank the Conservatoire du Littoral, the Syndicat Mixte des Espaces Littoraux de la Manche and the Syndicat Mixte Littoral Normand for their involvement in the project. We thank M.-F. Bernand, Y. Turgis, A. Guigny, E. Oulhen, A. Migné and the crew of Gwen Ha Ruz for their valuable help with fieldwork. This work received support from the “ATM Biodiversité des microorganismes”, and their support is gratefully acknowledged.
